**Abstract**

Cholesterol granuloma is an inflammatory reaction to cholesterol crystals deposition. It may develop in a variety of sites including the middle ear, mastoid process or even paranasal sinuses. Very few cases of cholesterol granuloma occurring in the jaws were reported. This report presents a rare case of cholesterol granuloma that developed in the wall of a large mandibular dentigerous cyst. The condition was treated with hemimandibulectomy followed by reconstruction with a free fibular flap.

**Key words**

Cholesterol granuloma, mandible, dentigerous cyst.

*Note: This report was presented during the 47th Congress of the Korean Association of Maxillofacial Plastic and Reconstructive Surgeons. April 2009, Seoul, Rep. of Korea.*

**Introduction**

Cholesterol granuloma represents an inflammatory foreign body reaction in response to cholesterol crystals. It usually develops in association with chronic middle ear diseases and affects the mastoid antrum and air cells within the temporal bone. However, it can rarely develop in the paranasal sinuses (1,2).

Only very few cases of cholesterol granuloma occurring in jaws were reported in the English literature. Here we present an extremely rare case of cholesterol granuloma within a mandibular dentigerous cyst wall.

**Case report**

A 68 years old male patient was referred to Seoul National University Dental Hospital, complaining of a chronic swelling in the left cheek area associated with cheek biting, of 2 years duration.

Clinical examination revealed thickening of the left buccal mucosa with traumatic ulceration due to chronic cheek biting.

Radiographic examination showed a large multilocular radiolucency surrounding a horizontally impacted third molar in the left side of the mandible (Fig. 1). The lesion was managed by hemimandibulectomy followed by reconstruction using a fibular free flap.

Mass gross specimen examination of the resected hemimandible from the lower right central incisor to the coronoid process showed cortical bone thinning, with 2 distinct parts. An anterior part containing a mud-like, grayish brown granulomatous material and an empty posterior part containing the left mandibular third molar. The size of the resected mass was 10.5 x 7.5 x 3.5 cm (Fig. 2).

Histologic examination of the resected tissue by light microscopy revealed that the posterior part of the lesion contained 3-5 layers of flattened non-keratinized epithelial cells surrounded by a thin fibrous capsule with no inflammatory cells. The anterior part, however, was completely occupied by cholesterol granulomatous tissue with heavy lymphocyte infiltration between the cholesterol clefts within a fibrous connective tissue stroma. No presence of epithelial cells was evident (Fig. 3). The presence of hemosiderin in the anterior part may be an evidence of previous hemorrhage. The final diagnosis of the resected lesion was a dentigerous cyst with cholesterol granuloma occupying its anterior part.
Differential diagnosis of multilocular radiolucencies within the jaws includes, but is not limited to, ameloblastomas, dentigerous cysts and odontogenic keratocysts. Dentigerous cysts are the most common developmental odontogenic cysts in the jaws. Although they are not true multilocular lesions, they can grow to a considerable size and give such an impression on radiographs due to the presence of bone trabeculation within the cystic cavity. Most commonly they develop in association with impacted mandibular third molars, less frequently with impacted maxillary canines or other teeth. Usually they are asymptomatic unless infected or growing to a considerable degree causing bony expansion and asymmetry (3).

Cholesterol granuloma describes a large collection of longitudinal clefts representing sites of cholesterol crystals that dissolved during processing, with surrounding foreign body giant cells and macrophages filled with hemosiderin and embedded in fibrous granulation tissue (4). It can develop in a variety of body areas such as: the middle ear (most common site), mastoid process testis, lungs, apex of temporal bone pyramid and paranasal sinuses (5).

Unlike cholesterol granuloma, development of ameloblastoma or even squamous cell carcinoma within dentigerous cysts have been previously reported (6,7).
The pathogenesis of cholesterol granuloma is still unclear, but in the middle ear it is seems to be related to obstruction of ear drainage. Disturbance of air drainage would cause negative pressure within the air cavity secondary to absorption of air into mucosa. As a result, mucosal edema and hemorrhage develop. Hematoma from the mucosal bleeding would not be absorbed, resulting in its conversion to cholesterol crystals. The deposited cholesterol crystals act as an irritant which attracts foreign body giant cells and causes fibrosis (2). Based on this mechanism, cholesterol granuloma is not expected to occur in the mandible due to the absence of intrabony cavities or drainage pathways.

A recent study by Yamazaki et al. (8) suggests that perlecan (a basement membrane heparan sulfate proteoglycan) which is present abundantly in the cyst wall of immature granulation tissue might be related to the development of cholesterol granulomas.

To the best of our knowledge, the case reported by Hirschberg et al. (9) is the only case of cholesterol granuloma reported in the mandible in English literature. Kaffe et al. (10) reported another case of cholesterol granuloma in a maxillary odontoma. This is the first reported case of cholesterol granuloma within a mandibular odontogenic cyst.
