Abstract
Ameloblastoma, a benign epithelial odontogenic tumor, is locally aggressive. This tumor comprises about 1% of tumors and cysts arising in the jaws. It appears most commonly in the third to fifth decades and with equal frequency between sexes. Ameloblastoma prevalently occurs in the mandibular molar and the ramus areas. Recurrence frequently appears after inadequate treatment. They are usually benign in growth pattern but frequently invade locally and occasionally metastasize. In the present study, a case of unusually large plexiform ameloblastoma was presented with its clinical, radiological, histological features and treatment modalities, and this is the addition of one more case in the literature.

Key words: Ameloblastoma, mandible, odontogenic tumors.
Introduction
Ameloblastoma is a true neoplasm of odontogenic epithelium (1). It represents about 1% of all oral ectodermal tumors and 9% of odontogenic tumors (2). It is an aggressive neoplasm that arises from remnants of the dental lamina and dental organ (odontogenic epithelium) (3). Most ameloblastomas develop in the molar-ramus region of the mandible with 70% of these arising in the molar-ramus area and they are occasionally associated with unerupted third molar teeth (4). Ameloblastoma appears most commonly in the third to fifth decades but the lesion can be found in any age group including children (2, 5).

The chief histopathological variants of ameloblastoma are the follicular and plexiform types, followed by the acanthomatous and granular cell types. Uncommon variants include desmoplastic, basal cell, clear cell ameloblastoma, keratoameloblastoma and papilliferous ameloblastoma (5). It is well known that ameloblastoma can be radiologically unilocular or multilocular radiolucency with a honeycomb or soap bubble appearance. The plexiform pattern is less aggressive and has a significantly lower recurrence rate (6).

Case report
A 12 year old girl had been reported to the Department of Oral Pathology and Microbiology with complaint of swelling on left side of face since last 2 years. The medical history was unremarkable. Clinical examination revealed diffuse, smooth –surfaced, hard swelling on left side of face. It extends from the zygomatic region to the inferior border of mandible superoinferiorly, and from the corner of mouth to the angle of mandible anteroposteriorly. It was large, expansive, and painless. It was covered by normal mucosa (Fig.1).

Intraorally, the swelling extends from distal of first molar posteriorly. Swelling results in obliteration of buccal vestibule.
Panoramic radiography showed a large multilocular radiolucent area occupying the left mandible from the first molar tooth to the neck of condylar process and the coronoid process including the left ascending ramus area. Root resorption was observed in the first molar. The base of the mandible and the anterior border of the ramus was damaged and thinned (Fig.2).

The histopathological processing of the tumor revealed a plexiform ameloblastoma predominantly composed of epithelium arranged as a tangled network of anastomosing strands. The cords or sheets of epithelium are bounded by columnar or cuboidal ameloblast like cells surrounding more loosely arranged epithelial cells. The
and was in second decade of her life. Clinically, it frequently manifests as a painless swelling, which can be accompanied by facial deformity, malocclusion, ulceration and periodontal disease and paresthesia of the affected area. In our case, clinical examination revealed a large, expansive mass in the ascending ramus and molar region of the mandible. The swelling was hard, painless to palpation and covered by normal mucosa.

Histologically, ameloblastoma is characterized by the proliferation of epithelial cells arranged in a collagenous fibrous connective tissue stroma of conjunctive vascular tissue in locally invading structures that resemble the enamel organ at different stages of differentiation (7). The tumor found in our patient was an ameloblastoma of the plexiform type. The term “plexiform” refers to the appearance of anastomosing islands of odontogenic epithelium in contrast to a follicular pattern.

Discussion
Ameloblastoma is a benign epithelial odontogenic tumor but is often aggressive and destructive, with the capacity to attain great size, erode bone and invade adjacent structures (7). Although the term ameloblastoma was coined by Churchill in 1933, the first detailed description of this lesion was by Falkson in 1879 (7). It is the most common odontogenic tumor although it represents only about 1% of tumors and cysts of the jaws (5).

In the mandible (80% of ameloblastomas), 70% are located in the area of the molars or the ascending ramus, 20% in the premolar region, and 10% in the anterior region (2). About 10-15% of ameloblastomas are associated with a non-erupted tooth. In the present case, a large plexiform ameloblastoma found in the ascending ramus and molar region of the mandible and it was not associated with a non-erupted tooth. Ameloblastoma appears equal frequency between sexes, although a higher frequency in females than in males has been described (7). In our case, the patient was female and was in second decade of her life. Clinically, it frequently manifests as a painless swelling, which can be accompanied by facial deformity, malocclusion, ulceration and periodontal disease and paresthesia of the affected area. In our case, clinical examination revealed a large, expansive mass in the ascending ramus and molar region of the mandible. The swelling was hard, painless to palpation and covered by normal mucosa.
